\section*{1. Introduction}

Different stress return algorithms have been proposed to integrate the constitutive relationships to compute the increments in stresses and state variables. One of the relatively easy algorithms is the so-called ‘explicit scheme’. This integration scheme enables the updated quantities at time $t + \Delta t$ to be calculated based on known quantities at time $t$. Its notable advantage is the simplicity in FE implementation and it has been widely used in geomechanics \cite{1}. However, the yield condition is not guaranteed at time $t + \Delta t$ in such a forward integration process. As a result, the calculated quantities, for instance the plastic multiplier at time $t + \Delta t$, is not satisfied in the yield condition. This causes the solution over many increments to drift away from the yielding surface \cite{2}. Moreover, the time step size, $\Delta t$, cannot be too large. Otherwise, incorrect results will be encountered. Therefore, the application of explicit schemes is usually limited to some simple constitutive models (e.g., linear elastic model). For complex non-linear constitutive models, the explicit scheme is usually neither efficient nor applicable despite that some researchers have been attempting to improve the performance of the explicit scheme. A good example is the explicit method with automatic substepping and error control as proposed by \cite{3} for a suction-dependent unsaturated soil model, and more recently by \cite{4} for integrating the well-known Barcelona Basic Model.

In contrast to the explicit scheme, another integration algorithm is called ‘fully implicit scheme’. In detail, an (elastic) trial stress increment is firstly computed to obtain the updated trial stress $\sigma_{tr}^{t+\Delta t}$. The trial stress will be outside the yield surface if the yield condition is not satisfied. On this occasion, the trial stress is then brought back onto the yield surface at time $t + \Delta t$ with a plastic correction. This is known as stress return process that must be solved iteratively, of which a widely used method is the Newton method. Fully implicit method ensures the yield condition that is satisfied at each time increment, thus avoiding the deviation from the yield surface, as commonly encountered in the explicit scheme. In addition, the fully implicit scheme allows for the use of significantly larger time increments, which can give rise to faster solutions \cite{2}. Note that the fully implicit method has been widely used in geomechanics \cite{5–7} and general complex elastoplastic and viscoplastic materials, and models of which the mechanical responses are determined by all principal stress invariants.

The constitutive equations can also be integrated using a backward Euler return algorithm \cite{6,8–14}. This might be considered to be a ‘semi-implicit’ method with first-order accuracy, as it still follows the idea of stress return but relies on the first-order of
2. Discussion of the breakage mechanics and simple breakage model

The significance of thermodynamics in the formulation and development of constitutive models has been widely acknowledged [15–18]. A rigorous constitutive model must satisfy both the first and second laws of thermodynamics in order to be consistent and physically meaningful. Otherwise, a model that does not obey the thermodynamics framework may not be used confidently in describing a material behaviour [16]. The importance of obeying thermodynamics framework in developing constitutive models has been recently stressed by Al-Rub and Darabi [19] and Darabi et al. [20], who established a general thermodynamically consistent framework for coupling various mechanisms such as temperature, viscoelasticity, viscoplasticity, viscodamage, and micro-damage healing for constitutive modelling of time- and rate-dependent materials.

On the other hand, the formulation of continuum breakage mechanics and simple breakage model [21,22] were developed on the basis of thermodynamics principles. Following the thermodynamics principles, the breakage mechanics emphasises the significance of linking micro to macro scales (i.e., avoiding as much as possible the arbitrary mathematical structures) in constitutive modelling by incorporating grain size distribution (GSD) and its evolution (through breakage, B) to capture the macroscopic soil behaviour. In this way, the underlying microscopic process connects with macroscopic behaviour, which many other continuum theories fail to capture.

There are various thermodynamically consistent breakage models that have been derived from the breakage mechanics, providing physical explanations for many of the phenomenological aspects of crushable soil behaviour. Thus, these models have far been used in different engineering applications, including geophysics [23,24], rock mechanics [25], foundation engineering [26], unsaturated soil mechanics [27], and a general breakage model accounting for finite deformation and porous compaction and dilation [28]. Among those breakage models, the focus of the present study is the simple breakage model that is the simplest and fundamental form among those breakage models, the focus of the present study is the simple breakage model that is the simplest and fundamental form among those breakage models, the focus of the present study is the simple breakage model that is the simplest and fundamental form among those breakage models.
where
- $K$ and $G$ respectively represent the bulk and shear moduli;
- $e_v^e$ and $e_s^e$ are the elastic volumetric and shear strains in triaxial conditions, respectively;
- $v$ (from 0 to 1) is a grading index which indicates the distance between the initial and ultimate GSD’s [21];
- $B$ (from 0 to 1) is a breakage index, an internal state variable in a thermodynamic sense. $B$ can be used to connect the current cumulative GSD (by mass), $F(x)$, with the initial cumulative GSD, $F_0(x)$, and ultimate cumulative GSD, $F_u(x)$ based on the grain sizes $x$, by a linear relationship [21]:

$$F(x, B) = (1 - B)F_0(x) + BF_u(x) \quad (2)$$

### 2.1. Constitutive equations

From the framework of thermodynamics [21,22,24], constitutive equations are defined by degrading elasticity equations as follows:

$$p = \frac{\partial \Psi}{\partial e_v} = (1 - \vartheta B)Ke_v^e \quad (3)$$

$$q = \frac{\partial \Psi}{\partial e_s} = 3(1 - \vartheta B)Ge_s^e \quad (4)$$

$$E_b = -\frac{\partial \Psi}{\partial B} - \frac{\vartheta}{2} \left(K e_v^{e^2} + 3 Ge_s^{e^2}\right) = \frac{\vartheta}{2(1 - \vartheta B)^2} \left(p^2 + q^2 + \frac{K}{3G}\right) \quad (5)$$

where
- $p$ and $q$ respectively represent the mean and triaxial shear stresses;
- $E_b$ is a breakage energy, a stress-like conjugate that describes the total stored free energy available for release from the granular aggregate fractured from the initial to ultimate states of GSD.

### 2.2. Energy dissipations

Energy dissipations describe energy losses of the granular materials during crushing process, which are accomplished through a rational mathematical formulation. The mathematical equations of energy dissipations have been presented and adopted by many existing relevant works [23,24,26] without sufficient details regarding their mathematical formulations. The following derivations are therefore presented to show their rationality in the formulations.

Breakage mechanics identifies three sources of energy dissipations of particle crushing in granular materials, i.e., particle breakage, plastic volumetric and shear strains (or deformations). In conventional rate-independent plasticity theory, the increments of plastic dissipations are assumed to be homogeneous first order functions of the plastic volumetric and shear strain increments, respectively:

$$\delta \Phi^u_p = \frac{\partial \delta \Phi^u_p}{\partial \delta e_v^p} \delta e_v^p$$

$$\delta \Phi^u_s = \frac{\partial \delta \Phi^u_s}{\partial \delta e_s^p} \delta e_s^p$$

(6)

(7)

where $\delta \Phi^u_p$ and $\delta \Phi^u_s$ denote the increments of plastic volumetric and shear dissipations via the change of incremental volumetric and shear strains, $\delta e_v^p$ and $\delta e_s^p$.

Analogous to the above formulations, the increment of breakage dissipation, $\delta \Phi^u_b$, is also assumed to take a first order homogeneous function [21]:

$$\delta \Phi^u_b = \frac{\partial \delta \Phi^u_b}{\partial \delta B} \delta B$$

(8)

where $\delta \Phi^u_b$ denotes the increment of breakage dissipation via the change of incremental breakage, $\delta B$.

On the other hand, the $p$, $q$ and $E_b$ can also be obtained from dissipation potential (in incremental form), $\delta \Phi$, based on the energy conservation equation [21]:

$$p = \frac{\partial \delta \Phi}{\partial \delta e_v^p}$$

(9)

$$q = \frac{\partial \delta \Phi}{\partial \delta e_s^p}$$

(10)

$$E_b = \frac{\partial \delta \Phi}{\partial \delta B}$$

(11)

In extreme cases where the energy loss is exclusively induced either by plastic volumetric, shear dissipation or breakage dissipation, Eqs. (9)–(11) become:

$$p = \frac{\partial \delta \Phi^u_p}{\partial \delta e_v^p}$$

(12)

$$q = \frac{\partial \delta \Phi^u_s}{\partial \delta e_s^p}$$

(13)

$$E_b = \frac{\partial \delta \Phi^u_b}{\partial \delta B}$$

(14)

Substituting Eqs. (12)–(14) into Eqs. (6)–(8), we have:

$$\delta \Phi^u_p = p \delta \delta e_v^p$$

(15)

$$\delta \Phi^u_s = q \delta \delta e_s^p$$

(16)

$$\delta \Phi^u_b = E_b \delta \delta B$$

(17)

In more general cases where the energy loss is a combination of the result from the three sources, a few modifications to Eqs. (15)–(17) are manipulated as follows:

- Under isotropic compression conditions, $\delta \Phi^u_p$ induced by particle-rearrangement passively arises from particle breakage, $\delta \Phi^u_b$ and then the both dissipation mechanisms compete (couple) with each other during fracture of granules. A coupling angle, $\omega$ (between 0° and 90°) is therefore introduced to describe the deviations between $\delta \Phi^u_p$ and $\delta \Phi^u_b$ [22]. Under shearing conditions, the induced dissipation $\delta \Phi^u_s$ is derived on the basis of Coulomb’s friction law.

- A mathematically favourable expressions of $\delta \Phi^u_p$ and $\delta \Phi^u_b$ can be formulated by incorporating the breakage-yield criterion, $E_b(1 - B)^2/E_c = 1$ [21]. Here $E_c$ is termed “breakage energy constant” obtained from critical isotropic confining pressure $p_c$ to initialise grain crushing of the aggregate via $p_c = 2KE_c/\vartheta$ [30].

Applying the above considerations to Eqs. (15)–(17) leads to:

$$\delta \Phi^u_b = \sqrt{\frac{E_b E_c}{(1 - B) \cos \omega}} \delta B$$

(18)

$$\delta \Phi^u_p = \frac{p}{(1 - B) \sin \omega} \sqrt{\frac{E_b \delta \delta e_v^p}{E_b}}$$

(19)

$$\delta \Phi^u_s = Mq \delta \delta e_s^p$$

(20)

where $M = q/p$, is the ratio of shear stress to the volumetric one at failure.
2.3. Plastic potential

Plastic potential $y^*$, or termed yield function in dissipative triaxial stress/breakage space, has been adopted by [23,24,26]. However, the detailed derivation has not been fully presented, leading to an incomplete understanding of the breakage mechanics and simple breakage model. In the following, we provide concise but essential steps to derive $y^*$ based on increment of dissipation potential $\delta \Phi$ that associates with $\delta \Phi_{y^*}$, $\delta \Phi_p$ and $\delta \Phi_{p^*}$.

In breakage mechanics, $\delta \Phi$ is a combination of coupling $\delta \Phi_{y^*}$, $\delta \Phi_p$ and $\delta \Phi_{p^*}$ together in a convenient form [24]:

$$\delta \Phi = \sqrt{(\delta \Phi_{y^*}^2 + \delta \Phi_p^2 + \delta \Phi_{p^*}^2)} = \sqrt{(\Delta_1 \delta B)^2 + (\Delta_2 \delta \varepsilon_{p}^{V})^2 + (\Delta_3 \delta \varepsilon_{p}^{H})^2}$$

(21)

where recalling Eqs. (18)–(20), we have:

$$\Delta_1 = \frac{\partial \delta \Phi_{y^*}}{\partial \delta B} = \frac{\sqrt{E_b E_c}}{(1-B) \cos \omega}$$

(22)

$$\Delta_2 = \frac{\partial \delta \Phi_p}{\partial \delta \varepsilon_{p}^{V}} = \frac{p}{(1-B) \sin \omega}$$

(23)

$$\Delta_3 = \frac{\partial \delta \Phi_{p^*}}{\partial \delta \varepsilon_{p}^{H}} = Mp$$

(24)

Eq. (21) can be rearranged as below:

$$\delta \Phi = \frac{\delta \Phi_{y^*}}{\delta B} \delta B + \frac{\delta \Phi_p}{\delta \varepsilon_{p}^{V}} \delta \varepsilon_{p}^{V} + \frac{\delta \Phi_{p^*}}{\delta \varepsilon_{p}^{H}} \delta \varepsilon_{p}^{H}$$

(25)

Eq. (25) proves that Eq. (21) is a first order homogenous function. From Eq. (21), we have:

$$\frac{\partial \delta \Phi}{\partial \delta B} \Delta_1^2$$

(26)

$$\frac{\partial \delta \Phi}{\partial \delta \varepsilon_{p}^{V}} \Delta_2^2$$

(27)

$$\frac{\partial \delta \Phi}{\partial \delta \varepsilon_{p}^{H}} \Delta_3^2$$

(28)

Using Eqs. (26)–(28), the Eq. (25) becomes:

$$\delta \Phi = \left( \frac{\partial \delta \Phi}{\partial \delta B} \right)^2 \delta \Phi \Delta_1^2 + \left( \frac{\partial \delta \Phi}{\partial \delta \varepsilon_{p}^{V}} \right)^2 \delta \Phi \Delta_2^2 + \left( \frac{\partial \delta \Phi}{\partial \delta \varepsilon_{p}^{H}} \right)^2 \delta \Phi \Delta_3^2$$

(29)

Based on Eq. (32), the plastic potential $y^*$ can be expressed as:

$$y^* = \left( \frac{\partial \delta \Phi_{y^*}}{\partial \delta B} \right)^2 \delta \Phi \Delta_1^2 + \left( \frac{\partial \delta \Phi_p}{\partial \delta \varepsilon_{p}^{V}} \right)^2 \delta \Phi \Delta_2^2 + \left( \frac{\partial \delta \Phi_{p^*}}{\partial \delta \varepsilon_{p}^{H}} \right)^2 \delta \Phi \Delta_3^2 - 1$$

(30)

Recalling Eqs. (9)–(11), $y^*$ can be replaced by:

$$y^* = \left( \frac{E_b}{\partial \delta \Phi_{y^*} / \partial \delta B} \right)^2 + \left( \frac{p}{\partial \delta \Phi_p / \partial \delta \varepsilon_{p}^{V}} \right)^2 + \left( \frac{q}{\partial \delta \Phi_{p^*} / \partial \delta \varepsilon_{p}^{H}} \right)^2 - 1$$

(31)

2.4. Non-associated flow rules

The non-associated flow rules are derived from the $y^*$ with the help of Eqs. (18)–(20):

$$\delta \Phi_y = \delta \Phi_p \frac{\partial y^*}{\partial \delta \Phi_p} = \delta \Phi_{p^*} \frac{\partial y^*}{\partial \delta \Phi_{p^*}} = \frac{2E_b (1-B)^2 \sin^2 \omega}{\rho E_c}$$

(32)

$$\delta \Phi_y = \delta \Phi_p \frac{\partial y^*}{\partial \delta \Phi_p} = \frac{2q}{(M_p)^2}$$

(33)

$$\delta \Phi_y = \delta \Phi_p \frac{\partial y^*}{\partial \delta \Phi_p} = \frac{2(1-B)^2 \cos^2 \omega}{E_c}$$

(34)

where $\delta \Phi_y$ is a non-negative multiplier. The plastic-breakage coupling angle coupling angle $\omega$ governs the energy consumption due to $\delta \Phi_p$ and $\delta \Phi_{p^*}$, $\omega = 0^\circ$ indicates that grain crushing completely dominates the energy loss, and otherwise, $\omega = 90^\circ$ indicates plastic volumetric strain completely dominates the energy loss in isotropic compression conditions.

2.5. Yield function

Substituting Eqs. (18)–(20) into (31), $y^*$ can be replaced by elastic-plastic-breakage yield function, $y$ in the mixed stress/breakage space [29,30]:

$$y = \frac{E_b}{E_c} (1-B)^2 + \left( \frac{q}{M_p} \right)^2 - 1 \leq 0$$

(35)

Note that although $y$ is derived from $y^*$, they are not the same for the purpose of differentiation. It is easy to prove that $\partial y^*/\partial \delta \Phi_p \neq \partial y/\partial \delta \Phi_p$ and $\partial y^*/\partial \delta \Phi_{p^*} \neq \partial y/\partial \delta \Phi_{p^*}$. An illustration to show the non-associated flow rules of the simple breakage model has been presented in [31].

As a summary of the above simple breakage model, it contains only five physically identifiable mechanical parameters: shear and bulk modulus $G$ and $K$, friction coefficient $M$, critical breakage energy constant $E_c$, and coupling angle $\omega$ between the friction and breakage dissipative processes. All of these parameters can be measured and calibrated using a single standard triaxial test involving a stage of isotropic compression followed by a stage of drained or undrained shear. In addition, the model responds to variations in the initial GSD through the grading (physical) index $\phi$.

3. Numerical implementation in FEA

In order to implement the simple elastic breakage constitutive model in FEA, we will describe herein the triaxial model in its tensorial form. Note the sign convention follows that of solid mechanics, where compression is negative for the implementation in ABAQUS. The triaxial stress and strain invariants read:

$$p = -\frac{1}{3} \sigma_{kk}$$

(36)

$$q = \sqrt{2 \sigma_{kk} s_{kk}}$$

(37)

$$e_v = -\sigma_{kk}$$

(38)

$$e_v = \frac{2}{3} e_{kk}$$

(39)

$$s_{kk} = \sigma_{kk} - \frac{1}{2} \sigma_{kk}$$

(40)

$$e_y = e_{kk} - \frac{1}{2} \delta_{kk}$$

(41)

The elastic component of the constitutive model as previously shown by Eqs. (3)–(5) can be rewritten in tensorial form, such that:

$$\sigma_{kk} = (1 - \nu B) D_{kk} e_{kk}$$

(42)
As can be seen, $(1 - \vartheta B)$ acts as a scalar degradation function of linear elastic equation, where the linear elastic stiffness matrix $D_{ijkl}$ remains:

$$D_{ijkl} = \begin{bmatrix}
    K + \frac{2}{3} G & K - \frac{2}{3} G & K - \frac{2}{3} G & K - \frac{2}{3} G \\
    K - \frac{2}{3} G & K + \frac{2}{3} G & K - \frac{2}{3} G & K - \frac{2}{3} G \\
    K - \frac{2}{3} G & K - \frac{2}{3} G & K + \frac{2}{3} G & K - \frac{2}{3} G \\
    0 & 0 & 0 & 2G
\end{bmatrix} \tag{43}$$

Differentiating $y'$ with respect to stresses, $\sigma_y$ and the thermodynamic conjugate, $E_\delta$ results in the following non-associated flow rules in tensorial forms:

$$\delta\sigma_{yy}' = \delta\sigma_y = \delta \left[ \frac{\partial y'}{\partial \sigma_y} \delta \sigma_y + \frac{\partial y'}{\partial \sigma_q} \delta \sigma_q \right]$$

$$= \delta \sigma_y \left[ 2(1-B)^2 E_\delta \sin^2 \omega \delta y_q + \frac{3}{2} \frac{3}{M^2 p^2} \right] = \delta \sigma_{yy} Q_{ij} \tag{44}$$

$$\delta \sigma_y = \frac{\delta y}{\delta E_\delta} = \frac{\partial y'}{\partial \sigma_y} 2(1-B)^2 \cos^2 \omega \delta y_q + \frac{3}{2} \frac{3}{M^2 p^2} = \delta \sigma_y R \tag{45}$$

In order to compute the stress increment $\delta \sigma_y$ based on the strain increment $\delta \epsilon_y$ obtained from the non-linear FEA at the current point X (refer to Fig. 1), first to consider the case where yielding occurs at a trial point Y, i.e., $y_{trial} > 0$. At this trial stress point, we assume a linear elastic behaviour with stiffness $(1 - \vartheta B) D_{ijkl}$ for $\delta \epsilon_y$ resulting in a trial stress increment $\delta \sigma_{yy trial} = (1 - \vartheta B) D_{ijkl} \delta \epsilon_{ijkl}$.

Following first-order Taylor expansion, the yield function at the trial point Y (Fig. 1) is written as:

$$y = y_{trial} + \frac{\partial y}{\partial B} \delta B + \left( \frac{\partial y}{\partial \sigma_y} \delta \sigma_y + \frac{\partial y}{\partial \sigma_q} \delta \sigma_q \right) \delta \sigma_{yy}$$

$$= y_{trial} + \frac{\partial y}{\partial B} \delta B + M_y \delta \sigma_{yy} \tag{46}$$

The stress return (acts as a plastic corrector) from the points Y to Z (Fig. 1), $\delta \sigma_{yy}$ is computed by:

$$\delta \sigma_{yy} = -(1 - \vartheta B) D_{ijkl} \delta \epsilon_{ijkl} - \frac{\partial y}{\partial \sigma_y} \delta B$$

$$= -\delta \sigma_y \left[ (1 - \vartheta B) D_{ijkl} \epsilon_{ijkl} + \frac{\partial y}{\partial \sigma_y} R \right] \tag{47}$$

Substituting Eq. (50) and the flow rule Eq. (48) into Eq. (49) results in:

$$y = y_{trial} + \frac{\partial y}{\partial B} R - M_y \left( (1 - \vartheta B) D_{ijkl} \epsilon_{ijkl} + \frac{\partial y}{\partial \sigma_y} R \right) \delta \sigma_y \tag{48}$$

where $\epsilon_{ijkl}$ and $R$ are defined in Eqs. (43)–(45). By doing so, the implication is that all variables and quantities in Eq. (46) are simply evaluated at a trial point Y. Imposing the yield condition at point Z, $y = y_Z = 0$, we can obtain the multiplier $\delta \sigma_y$ as follows:

$$\delta \sigma_y = \frac{y_{trial} - y_Z}{(1 - \vartheta B) D_{ijkl} \epsilon_{ijkl} + \frac{\partial y}{\partial \sigma_y} R} \tag{49}$$

At last, the total stress increment, $\delta \sigma_{yy}$ as the sum of $\delta \sigma_{yy trial}$ and $\delta \sigma_{yy}$ (Fig. 1) is given as follows:

$$\delta \sigma_{yy} = \delta \sigma_{yy trial} + \delta \sigma_{yy} \tag{50}$$

The above algorithm has been fully implemented in UMAT, a widely used platform of user subroutine embedded into the commercial finite element package ABAQUS in this paper.

Note that due to the linearization (i.e., first-order Taylor expansion) of the yield function in Eq. (46), the returned stress point $Z$ usually does not exactly lie on the new yield surface, e.g., $y(Z), y_{trial}, q_Z \neq 0$; however, sufficient accuracy can be achieved with a relatively large increment, like $\Delta \epsilon_a = 10^{-2}$, which will be demonstrated later in Section 4.5. Alternatively, repetition of the above process, e.g., linearizing the yield function at point Z and then following the same algorithm is a simple way to reduce the gap between the stress point and the yield surface. Improvement to the accuracy can also be made by dividing the total strain increment $\delta \epsilon$ into sub-increments, and applying the above algorithm to each sub-increment.

3.1. Tangent stiffness matrix

Implicit finite element analysis using the Newton-Raphson iterative techniques requires the formulation of the tangent stiffness matrix (Jacobian). This matrix is of importance to increase the convergence rate. The derivation of Jacobian is straightforward by starting from the stress-strain relationship (Eq. (42)) written in:

$$\delta \sigma_y = (1 - \vartheta B) D_{ijkl} (\delta \epsilon_{ijkl} - \delta \epsilon_{ijkl}) - \delta \sigma_{yy trial}$$

$$= (1 - \vartheta B) D_{ijkl} \delta \epsilon_{ijkl} - (1 - \vartheta B) D_{ijkl} \delta \epsilon_{ijkl} - \delta \sigma_{yy trial}$$

$$= (1 - \vartheta B) D_{ijkl} \delta \epsilon_{ijkl} - \delta \sigma_{yy trial} \tag{51}$$

Substituting Eqs. (47) and (48) into the above:

$$\delta \sigma_y = (1 - \vartheta B) D_{ijkl} \delta \epsilon_{ijkl} - (1 - \vartheta B) D_{ijkl} \delta \epsilon_{ijkl} - \delta \sigma_{yy trial}$$

$$\delta \sigma_y = (1 - \vartheta B) D_{ijkl} \delta \epsilon_{ijkl} - (1 - \vartheta B) D_{ijkl} \delta \epsilon_{ijkl} - \delta \sigma_{yy trial} \tag{52}$$

As opposed to Eq. (46) in implicit integration, consistency condition in explicit integration is generally obtained as:

$$\delta \sigma_y = \frac{\partial y}{\partial B} \delta B + M_y \delta \sigma_y \tag{53}$$

Substituting Eq. (52) and flow rule Eq. (45) into Eq. (53), we have:

$$\delta \sigma_y = \frac{\partial y}{\partial B} \delta B + M_y \delta \sigma_y \tag{54}$$

The plasticity/breakage multiplier is then:

$$\delta \lambda = \frac{1}{(1 - \vartheta B) M_y D_{ijkl} \delta \epsilon_{ijkl} + \frac{\partial \sigma_y}{\partial \vartheta B} R} \tag{55}$$

Placing Eq. (55) into Eq. (52), we obtain:

$$\delta \sigma_y = \left( (1 - \vartheta B) D_{ijkl} - (1 - \vartheta B) D_{ijkl} \epsilon_{ijkl} + \frac{\partial \sigma_y}{\partial \vartheta B} R \right) \delta \sigma_{ijkl} \tag{56}$$

$T_{ijkl}$ is defined in Eq. (55). Thus the tangent stiffness matrix is:

$$X_{ijkl} = (1 - \vartheta B) D_{ijkl} - (1 - \vartheta B) D_{ijkl} \epsilon_{ijkl} + \frac{\partial \sigma_y}{\partial \vartheta B} R \tag{57}$$
where the used notations and derivatives are listed below:

\[
\frac{\partial y}{\partial B} = \frac{\phi(1 - B)}{E_c(1 - \phi B)^2} \left( p^2 + \frac{q^2}{3}ight)
\]

(58)

\[
\frac{\partial y}{\partial p} = \frac{p \phi}{KE_c(1 - \phi B)^2} - \frac{2q^2}{M^2 p^2}
\]

(59)

\[
\frac{\partial y}{\partial q} = \frac{q \phi}{3GE_c(1 - \phi B)^2} + \frac{2q^2}{M^2 p^2}
\]

(60)

\[
\frac{\partial p}{\partial \sigma_{ij}} = -\frac{\delta_{ij}}{3}
\]

(61)

\[
\frac{\partial q}{\partial \sigma_{ij}} = \frac{\partial q}{\partial \sigma_{kl}} = \frac{3 s_{ij}}{2 q}
\]

(62)

\[
M_{ij} = \left( \frac{\partial p}{\partial B} \right)_{ij} D_{ijkl} \delta_{kl}
\]

(63)

\[
T_{kl} = \left( 1 - \phi B \right) D_{ijkl} Q_{kl}
\]

(64)

\[
N = \frac{\partial y}{\partial B} R - M_{ij} \left( 1 - \phi B \right) D_{ijkl} Q_{kl} + \frac{\partial y_{ij}}{1 - \phi B} R
\]

(65)

As can be seen from the above process, the implementation of the breakage model follows a standard procedure of stress return algorithm as a result of the versatile model formulation that obeys the thermodynamics. Therefore, the model can be relatively simply implemented without adding extra numerical difficulty, and be readily used in various numerical applications in FEA.

4. Verification of implementations

To verify the FE implementation, it is necessary to test the model’s response at the material point level using a single reduced integrated axisymmetric element, under various loading paths. To do this, the following four numerical experiments were conducted and the results obtained were compared with solutions from the triaxial model in generalized \( p-q-B \) space.

The schematics of the single-element model for all verification cases are shown in Fig. 2, in which only a quarter of the whole is modelled; while the boundary conditions vary from case to case, and they are illustrated in each case. The parameters, if not specified, are from parameters as listed in Table 1 that are cited from [24].

4.1. Isotropic loading condition

As the simplest case, the isotropic loading condition is firstly applied to validate the implementation. The model’s boundary conditions are shown in Fig. 3. Increase confining pressure \( p \) until a volumetric strain of \( \varepsilon_v = 0.5 \). The model’s mechanical responses are compared in Fig. 4.

4.2. Isotropic loading-unloading-reloading condition

While based on the same geometry used in Fig. 3, in this case we firstly compress the sample until \( \varepsilon_{v1} = 0.3 \), then unload the model until \( \varepsilon_{v2} = 0.15 \) (here ‘unloading’ is realised by adding an increased isotropic tensile pressure), and finally recompress the model until \( \varepsilon_{v3} = 0.6 \) (see Fig. 5).

4.3. Conventional drained loading with constant confining pressure

The boundary conditions for this case are illustrated in Fig. 6, in which the model is firstly under an initial isotropic stress of $p_0 = 100$ MPa. The model is then subjected to an increased shear stress $\Delta q$ till the shear strain $\varepsilon_s = 0.3$. The model’s responses to the triaxial model and finite element model (FEM) are compared in Fig. 7.

Fig. 7. Validation of implementation in terms of (a) \( q - \varepsilon_s \), (b) \( p - \varepsilon_v \), (c) \( p - q \) and (d) \( p - B \) relationship, under conventional drained loading condition.

Fig. 8. Validation of implementation in undrained loading condition in terms of (a) \( p - q \), (b) normalized shear stress and shear strain relationship, \( q/\sigma_r \), and (c) normalized volumetric stress and breakage relationship, \( p/\sigma_c \). Recall that \( p_c = \sqrt{2KE_c/\#} \). The following parameters were used: \( K = 30,000 \) kPa, \( G = 10,000 \) kPa, \( E_c = 50 \) kPa, \( M = 1 \), \( \# = 0.9 \) and \( \omega = 0^\circ \) (indicating no plastic volumetric strain).
4.4. Conventional undrained loading with constant confining pressure

The FE undrained model is also based on Fig. 6. To simulate the undrained behaviour of the soil model, all boundaries are impermeable. Therefore the permeability, \(k\), can be defined arbitrarily. Let us take \(k = 0.002\) m/s. Increase the shear stress \(\Delta q\) till the \(\varepsilon_s = 1.0\). The results from the FEM and triaxial models are compared in Fig. 8.

4.5. Accuracy verification

To validate the accuracy of the implementation, different \(\Delta \varepsilon_s\) (i.e. from \(10^{-1}\) to \(10^{-5}\)) are selected for the conventional undrained test. As an example, only the results of \(q/p_c\) and \(p/p_c - B\) are plotted in Fig. 9. It can be seen that good convergence is observed for \(\Delta \varepsilon_s\) less or equal to \(10^{-2}\). For \(\Delta \varepsilon_s\) equal or less than \(10^{-3}\), the results coincide with each other. Given \(\Delta \varepsilon_s = 10^{-3}\), the corresponding yielding value, \(y\) (Eq. (12)) is about \(10^{-4}\) that satisfies the requirement of numerical accuracy. Therefore, all simulations throughout this paper consider the both conditions of \(\Delta \varepsilon_s = 10^{-3}\) and \(y = 10^{-4}\) as the accuracy criterion.

5. Model application

The behaviour of two typical calcareous soils, Dog’s Bay and Chiibishi sands, and Bentheim sandstone are predicted using the
above FE model. The consolidated drained triaxial behaviour of these soils are simulated when they are subjected to different initial confining pressures. The single-element model is shown in Fig. 2 and boundary conditions in Fig. 6. The model’s parameters listed in Table 2 are mainly from [32–34], respectively. The index property $\psi$ for Dog’s Bay sand can be calculated based on the initial and ultimate cumulative GSDs, while that for Chibishib sand is determined from the experimentally given initial cumulative GSD, and an assumed fractal ultimate cumulative GSD in equation $F(x) = (x^{3-\alpha} - D_m^{3-\alpha})/(D_m^{3-\alpha} - D_m^{3-\alpha})$ where $D_m$ and $D_m$ denote the minimum and maximum size of grains and the fractal dimension $\alpha$ takes the value $\alpha = 2.7$ [35]. The high value $\psi$, for Bentheim sandstone implies very poor initial grading in the test.

Figs. 10 and 11 show the agreement between numerical predictions and experimental observations. From these examples, we can see that the simple breakage model is particularly suitable for studying crushable granular aggregates, independent of their hardnesses.

The above numerical examples at the material point level are only used to illustrate the fundamental features of the simple breakage model. Comparatively, with the introduced implementation of the breakage model in various FEAs, some complicated non-uniform BVPs have been numerically studied elsewhere. To avoid any repetition and align with the focus of the paper, these complicated BVPs are not reproduced here. Interested readers are referred to recent papers that discuss each application of the model in detail. For instance [26], explored the crushing profile around a pile penetrating into crushable sands, while [36] focuses on energy-related crushing phenomenon of minerals passing through a roller mill. Furthermore, an open issue of grain crushing induced compaction localization in porous sandstones has been studied by [23] based on classical discontinuous bifurcation condition. A more recent work by [31] incorporated orientation of localised failure and size effect in the constitutive modelling of the simple breakage model.

6. Summary

The recently developed breakage mechanics and the simple breakage model have been discussed, with the focus on how to formulate the mathematical formulations of energy dissipations due to particle breakage, plastic volumetric and shear deformations, and plastic potential. These mathematical details that could have been missed partially or fully in the existing relevant works are elaborated in the present study. This is followed by the detailed illustration of the numerical implementation (with the backward Euler return algorithm) of the model in FEA. Subsequently, numerical tests are presented to demonstrate the efficiency of the implementation at the material point level (single element). Next, the key features of the simple breakage model to reflect the mechanical behaviour of granular materials was illustrated by comparing three crushable materials of varying hardness, ranging from very soft (calcareous sands) to very hard (sandstone). More complicated boundary values problems associating with grain crushing could readily be performed with the implemented breakage model, as preliminarily evidenced by [26] on piled foundation and [36] on mineral crushing and on localisation bands [23,31]. Nevertheless, some other open interesting issues such as nucleation and multi-physical field problems are beyond the capability of the current model, which may require further studies on kinematic behaviours of granular materials.
